Chemical Abundances of Red Giant Stars in the Globular Cluster M107 (NGC 6171)

JULIA E. O’CONNELL,¹ CHRISTIAN I. JOHNSON,^{2,3,4} CATHERINE A. PILACHOWSKI,³ AND GEOFFREY BURKS^{1,5}

Received 2011 June 17; accepted 2011 July 29; published 2011 September 20

ABSTRACT. We present chemical abundances of Al and several Fe-Peak and neutron-capture elements for 13 red giant branch stars in the Galactic globular cluster NGC 6171 (M107). The abundances were determined using equivalent width and spectrum synthesis analyses of moderate-resolution ($R \sim 15,000$), moderate signal-to-noise ratio ($\langle S/N \rangle \sim 80$) spectra obtained with the WIYN telescope and Hydra multifiber spectrograph. A comparison between photometric and spectroscopic effective temperature estimates seems to indicate that a reddening value of $E(B - V) = 0.46$ may be more appropriate for this cluster than the more commonly used value of $E(B - V) = 0.33$. Similarly, we found that a distance modulus of $(m - M)V \approx 13.7$ provided reasonable surface gravity estimates for the stars in our sample. Our spectroscopic analysis finds M107 to be moderately metal-poor with $\langle [Fe/H] \rangle = -0.93$ and also exhibits a small star-to-star metallicity dispersion ($\sigma = 0.04$). These results are consistent with previous photometric and spectroscopic studies. Aluminum appears to be moderately enhanced in all program stars ($\langle [Al/Fe] \rangle = +0.39$, $\sigma = 0.11$). The relatively small star-to-star scatter in $[Al/Fe]$ differs from the trend found in more metal-poor globular clusters, and is more similar to what is found in clusters with $[Fe/H] \gtrsim -1$. The cluster also appears to be moderately r -process-enriched with $\langle [Eu/La] \rangle = +0.32$ ($\sigma = 0.17$).

1. INTRODUCTION

The old paradigm that globular clusters represent single coeval stellar populations has been overturned by the discovery of multiple discrete populations existing in seemingly “normal” clusters (e.g., see Renzini 2008; Piotto 2009; Milone et al. 2010 for recent reviews). While it has long been known that essentially all globular clusters exhibit significant star-to-star abundance variations for the elements from carbon to aluminum (e.g., see Gratton et al. 2004 and references therein), the connection between the light-element variations and existence of multiple populations is only now becoming more clear. It is now thought that most clusters contain (at least) two separate generations of stars. These populations exhibit identical $[Fe/H]$ ⁶ ratios,

but differ in their light-element abundances (e.g., Carretta et al. 2009a). The first-generation, or “primordial,” stars reflect the light-element abundance patterns produced by Type II supernovae (SNe), which are nearly identical to the metal-poor halo composition. The second-generation stars appear to have formed from gas that experienced varying degrees of high-temperature proton-capture nucleosynthesis and are therefore, in general, O/Mg-poor and Na/Al-rich compared with the typical halo field star. Interestingly, the second generation tends to be the dominant population in most clusters, and the number of first-generation stars retained is likely a function of cluster mass (Carretta et al. 2009a). While the more massive clusters tend to exhibit the most extreme light-element abundance and multiple population characteristics, smaller clusters like M107, which do not appear to contain a significant fraction of extremely O/Mg-poor and Na/Al-rich stars, may be useful probes for determining the processes that produce the second generation in globular clusters.

The Galactic globular cluster M107 is of relatively average mass ($\sim 10^5 M_{\odot}$; Piatek et al. 1994), but is a factor of 2 more metal-rich than the average globular cluster (Harris 1996; updated 2010⁷). A compilation of multiple photometric and moderate-resolution spectroscopic analyses (Pilachowski et al.

1981; Smith & Perkins 1982; Smith & Manduca 1983; Zinn & West 1984; Carretta & Gratton 1997; Ferraro et al. 1999; Carretta et al. 2009a, 2009b) yields a metallicity value between $[\text{Fe}/\text{H}] = -0.83$ and -1.07 . However, most of the spectroscopic measurements are based on small sample sizes ($\lesssim 5$ stars). Although globular clusters tend to exhibit a wide range in horizontal branch (HB) morphologies at a given metallicity, the HB of M107 is dominated by red HB and RR Lyrae stars (Sandage & Katem 1964; Dickens & Rolland 1972; Sandage & Roques 1984; Da Costa et al. 1984; Ferraro et al. 1991; Cudworth et al. 1992), which is clearly reflected in the $(B - R)/(B + V + R)$ HB ratio estimate by Lee et al. (1994) of -0.76 ± 0.08 . M107 lacks a significant population of blue HB and blue hook stars that are typically found in some of the more massive clusters exhibiting the largest light-element abundance variations and may suggest that this cluster did not experience strong helium enrichment.

While the $[\text{Fe}/\text{H}]$, $[\text{O}/\text{Fe}]$, and $[\text{Na}/\text{Fe}]$ ratios have been determined for ~ 30 red giant branch (RGB) stars in M107, chemical abundances for Al and heavier α elements are only available for approximately five stars, and the neutron-capture element abundances have never been explored. Therefore, for the first time, we present moderate-resolution spectroscopic abundances of Al, Ti, Sc, Ni, Fe, La, and Eu for 13 RGB stars in this cluster. In § 2 we describe the selection of stars for observation and data reduction. Section 3 contains the radial velocity measurements and cluster membership evaluations for individual stars. Section 4 describes the procedures for estimating model atmosphere parameters and measuring the chemical abundances. Finally, in § 5 we outline and discuss the results and provide a summary in § 6.

2. OBSERVATIONS AND REDUCTIONS

The observations for all cluster giants were taken at Kitt Peak National Observatory on 2000 May 14 using the WIYN 3.5 m telescope instrumented with the Hydra multi-fiber positioner and bench spectrograph. All spectra were obtained with a single Hydra configuration that employed the 2" red fibers, 316 line mm^{-1} echelle grating, and red camera, achieving a resolving power of $R(\lambda/\Delta\lambda) \approx 15,000$. The spectrograph setup was centered near 6660 Å, and the full wavelength coverage spanned from ~ 6460 –6860 Å. Target stars were selected based on photometry from Sandage & Katem (1964), with colors suggesting their location on or near the RGB. The coordinates used in generating the Hydra configuration were taken from the USNO Image and Catalogue Archive.⁸ The final sample includes 13 RGB stars spanning a V magnitude range of 13.23–14.66, which corresponds to a luminosity range from the RGB tip down to approximately 1 mag above the level

⁸The Catalogue Archive Service can be found at <http://www.nofs.navy.mil/data/fchpix/>.

of the HB ($V_{\text{HB}} \approx 15.7$; Buonnano et al. 1989; Ferraro et al. 1991; see also Fig. 1).

Basic data reductions were carried out using the standard IRAF⁹ routines. Specifically, `ccdproc` was used to apply the bias-level correction and trim the overscan region. The IRAF task `dohydra` was employed for aperture tracing, scattered light and cosmic-ray removal, extraction of the one-dimensional spectra, flat-fielding, wavelength calibration (based on a ThAr comparison source), and sky subtraction. The extracted spectra were then co-added to increase the signal-to-noise ratio (S/N) of the final spectra and continuum fit using a low-order spline function. The S/N of the combined spectra ranged from ~ 60 –110.

3. RADIAL VELOCITY MEASUREMENTS AND CLUSTER MEMBERSHIP

Cluster membership was confirmed by comparing radial velocity measurements with the mean value of -34.23 km s^{-1} found by Pryor & Meylan (1993). All radial velocities for this study were determined via the IRAF task `fxcor` and were corrected for the Earth's motion using `rvcorrect`. A proper-motion study by Cudworth et al. (1992) presents membership probabilities for all stars selected for analysis, with the exception of star 201. Table 1 provides radial velocity measurements and associated uncertainties for each program star, as well as Cudworth's membership probabilities. The average radial

velocity of -31.8 km s^{-1} and small velocity dispersion ($\sigma = 2.4 \text{ km s}^{-1}$ found here are in agreement with previous studies (e.g., Pryor & Meylan 1993; Piatak et al. 1994).

Note that Smith & Hesser (1986) exclude star *F* as a cluster member based on DDO photometry and identified it as a possible foreground dwarf. However, Cudworth et al. (1992) assigned the star a high membership probability (98%), and we find star *F* to have a radial velocity that is reasonably consistent with the cluster average at -37.1 km s^{-1} . Although the radial velocity of star *F* is $\sim 2\sigma$ outside the cluster mean, it has an effective temperature, surface gravity, and metallicity that are all consistent with the star being a bona fide member. Therefore, we have included it in our analysis.

4. ANALYSIS

We have analyzed a small sample of RGB stars in M107 for elemental abundances of Al, neutron-capture, and Fe-peak elements in the range of Al to Eu II. IRAF's `splot` package was used to measure equivalent widths (EWs) with a single-line EW analysis for unblended lines and with a blended-line function for heavily blended lines or lines subject to hyperfine splitting. The wavelength range of observed spectra is from $\sim 6460\text{--}6860 \text{ \AA}$. Effective temperatures and surface gravities for individual stars were initially estimated using the cluster's distance modulus and $(V - K)_0$ color indices obtained from photometric data. Although Sandage & Katem (1964) provide photometry for all target stars, photometry for initial T_{eff} estimates was taken from the more recent proper-motion study by Cudworth et al. (1992). Star 201 was not included in this study, but Dickens & Rolland (1972) provide colors for 201 trans-

 TABLE 2
 ABUNDANCE SENSITIVITY TO MODEL ATMOSPHERE PARAMETERS

formed from Sandage & Katem (1964). An iterative LTE stellar line analysis program was used to further modify T_{eff} and microturbulence (v_t) via spectroscopic analyses. Table 2 shows the results of an assessment with respect to abundance sensitivity and associated uncertainties in adopted model atmosphere parameters for all elements considered in this study.

4.1. Model Stellar Atmospheres

Initial T_{eff} estimates for individual stars were determined through use of the empirical $V - K_S$ color-temperature relation described by Alonso et al. (1999, and erratum from 2001). The V -band photometry was obtained from Cudworth et al. (1992) and Dickens & Rolland (1972), and the K_S -band data were taken from the Two Micron All Sky Survey (2MASS) database (Skrutskie et al. 2006). A color excess value of $E(B - V) = 0.33$ (Webbink 1985; Harris 1996), which is in agreement with the Cudworth et al. (1992) estimate, was initially adopted in order to correct for interstellar reddening and extinction. However, we found that applying this reddening correction produced T_{eff} values that were at least 150–200 K lower than the T_{eff} estimates derived spectroscopically by imposing excitation equilibrium (see Fig. 2). Further investigation of this problem revealed that the color excess for NGC 6171 is not particularly well constrained, with literature values ranging from $E(B - V) \approx 0.25\text{--}0.50$ (e.g., Smith & Hesser 1986; Salaris & Weiss 1997). Dutra & Bica (2000) noticed a similar inconsistency between their derived value of $E(B - V) = 0.45$, based on 100 μm dust emission, and previously published estimates.

While our data do not permit an explicit measure of interstellar reddening along the cluster's line-of-sight, we do find that a near 1:1 correlation between photometric and spectroscopic T_{eff} estimates for cluster giants can be achieved if one assumes a reddening near the upper limit of $E(B - V) \approx 0.46$ (see Fig. 2). Since this larger $E(B - V)$ value is also found in the Schlegel et al. (1998) dust maps, which were accessed via the NED Coordinate Transformation & Galactic Extinction Calculator,¹⁰ we used an average value of $E(B - V) = 0.46$ in the final T_{eff} calculations. Furthermore, use of the online extinction calculator

¹⁰ See <http://nedwww.ipac.caltech.edu/forms/calculator.html>.

FIG. 2.—Dashed diagonal line represents perfect agreement between photometric estimates of effective temperature and T_{eff} derived spectroscopically. Open circles depict stellar T_{eff} models using a reddening value more commonly found in literature for this cluster, $E(B - V) = 0.33$. Filled circles along the diagonal represent the results of photometric T_{eff} estimates using $E(B - V) = 0.46$ and our final effective temperatures derived for each star.

permitted a rough examination into the prospect of differential reddening across our observed field, which could be an issue given the cluster's low Galactic latitude ($b = 23^\circ$). Fortunately, the star-to-star reddening variation did not exceed 0.02 mag, and therefore no additional corrections were applied.

Surface gravities were calculated using the standard relation,

$$\log(g) = 0.40(M_{\text{bol}} - M_{\text{bol}\odot} + \log(g_{\odot}) + 4(\log(T/T_{\odot})) + \log(M/M_{\odot})), \quad (1)$$

and assumed a stellar mass of $0.8 M_{\odot}$. Stellar atmospheres were modeled without convective overshoot by interpolating in the ATLAS9 grid¹¹ (Castelli et al. 1997). The absolute bolometric magnitudes (M_{bol}) were determined by applying the V -band bolometric corrections from Alonso et al. (1999; their eqs. [17] and [18]) to the absolute V -band magnitudes estimated from the distance modulus ($m - M)_V = 13.76$ (Shetrone et al. 2009). In a similar fashion to the reddening estimate, a wide range of distance modulus estimates for this cluster appear in the literature and span from $(m - M)_V = 15.06$ (e.g., Harris 1996) to $(m - M)_V = 13.76$ (Shetrone et al. 2009). However, we chose the smallest available distance modulus because the larger distance moduli yielded surface gravity values that appeared too low for each star's metallicity and position on the color-magnitude diagram.

¹¹ Kurucz model atmospheres can be found at <http://kurucz.harvard.edu/grids.html>.

Initial model atmospheres were calculated with a metallicity of $[\text{Fe}/\text{H}] \approx -1$, which is consistent with previous estimates (e.g., Smith & Manduca 1983; Pilachowski 1984; Zinn & West 1984; Ferraro et al. 1991; Carretta et al. 2009a, 2009b), and also assumed a microturbulence value of 2 km s^{-1} for all stars. These values were further refined through an iterative process that primarily focused on finalizing the microturbulence value by removing trends in Fe I abundance as a function of reduced width $[\log(\text{EW}/\lambda)]$. A summary of our final model atmosphere parameters and photometric indices is provided in Table 3.

4.2. Equivalent Width Analyses, Hyperfine Structure, and Spectrum Synthesis

All element abundances, with the exception of Al, were derived by EW measurements using IRAF's `splot` package. Suitable lines were chosen both by visual inspection and comparison with the Hinkle et al. (2000) Arcturus atlas, which combines a side-by-side profile of the solar and Arcturus spectra. Given the moderate resolution of our spectra, we chose lines for analysis that were not expected to be severely blended. While the abundances of Ti, Fe, Ni, and La were determined by employing the `abfind` driver in the 2002 version of the LTE line analysis code MOOG (Sneden 1973), the abundances of Al, Sc, and Eu were either determined via the `synth` spectrum synthesis driver (Al) or the blended line `blends` driver (Sc and Eu).

For Al, we chose to derive the abundances using full spectrum synthesis of the 6690–6700 Å window, because both the 6696 and 6698 Å Al lines are moderately blended with nearby metal and CN lines. For Sc, La, and Eu, the abundance derivation requires taking into account hyperfine structure and/or isotopic broadening. While both Sc and La have only one long-lived, stable isotope (⁴⁵Sc and ¹³⁹La), Eu has two (¹⁵¹Eu and ¹⁵³Eu) that are present in nearly equal proportions. Therefore, our input line lists for Sc and Eu made use of the the hyperfine/isotope data from Prochaska & McWilliam (2000) and Lawler et al. (2001), respectively. Although no hyperfine line list exists for the 6774 Å La II line used here, we applied the empirical correction given in Johnson & Pilachowski (2010; eq. [A1]) to our measured EWs. The final EWs and abundance ratios, cited as relative to Fe I, are provided in Tables 4 and 5, respectively.

5. RESULTS AND DISCUSSION

5.1. Al Abundances

Large star-to-star light-element abundance variations are a ubiquitous feature of globular clusters (e.g., see reviews by Kraft 1994; Gratton et al. 2004). While it is understood that these abundance patterns (in particular, those involving the elements between carbon and aluminum, are the result of proton-capture nuclear reactions), the exact production sites are not well established. Evolved red giants have deep convective envelopes that can mix proton-capture cycled material from a

^aStar identifiers are from Sandage & Katem (1964).

^bPhotometry for all stars except 201 is from Cudworth et al. (1992). Photometry for star 201 is from Dickens & Rolland (1972).

star's interior to its photosphere, and this mechanism is clearly responsible for the first dredge-up phenomenon (e.g., Iben 1965). However, observations of similar abundance variations involving heavier elements, from O to Al, in globular cluster stars near the main-sequence and turnoff (e.g., Cannon et al. 1998; Gratton et al. 2001; Cohen et al. 2002; Briley et al. 2004a, 2004b; Boesgaard et al. 2005) suggest that pollution must play a key role as well. The most commonly suggested pollution sites tend to be either rapidly rotating, massive stars (e.g., Maeder & Meynet 2006) or ~ 5 – $8 M_{\odot}$ asymptotic giant branch (AGB) stars (e.g., Ventura & D'Antona 2009). While the AGB scenario tends to be the most commonly accepted, it is likely that both massive and intermediate-mass stars play key roles in determining the light-element composition of globular cluster stars (see also Renzini 2008 for a recent review). Since Al is the heaviest element that generally exhibits a large abundance range in globular clusters, it requires the highest temperatures to be produced ($\gtrsim 5 \times 10^7$ K) in significant quantities. These temperatures are not expected to be reached at the bottom of the convective envelope in low-mass stars with $[\text{Fe}/\text{H}] \approx -1$, and therefore Al can be used as a tracer for the amount of pollution experienced by M107 stars.

We find the individual $[\text{Al}/\text{Fe}]$ ratios to be enhanced by an average of $+0.39$ dex with a relatively small dispersion of $\sigma = 0.11$ dex. While the full range of $[\text{Al}/\text{Fe}]$ spans from $+0.24$ to $+0.63$ dex, only two stars (*J* and 205) have $[\text{Al}/\text{Fe}] > +0.5$. The enhancement of Al in star 205 is shown in Figure 3, where we overplot stars *N* and 205, which have similar T_{eff} , $\log(g)$, and $[\text{Fe}/\text{H}]$, but differ in their $[\text{Al}/\text{Fe}]$ ratios by ~ 0.3 dex.

In Figure 4 we show a box plot of the $[\text{Al}/\text{Fe}]$ ratios for 13 globular clusters ranging in $[\text{Fe}/\text{H}]$ from approximately -2.35 to -0.80 . While it is clear from Figure 4 that the overwhelming majority of globular cluster stars have $[\text{Al}/\text{Fe}] > 0$, there

appears to be a significant change in the $[\text{Al}/\text{Fe}]$ abundance spreads for the more metal-rich clusters, including M107. The metal-poor, and generally more massive, clusters tend to exhibit a full range of $[\text{Al}/\text{Fe}]$ abundances spanning nearly a factor of 10, but the clusters with $[\text{Fe}/\text{H}] \gtrsim -1.2$ tend to exhibit abundance spreads of only 0.1–0.5 dex. This observation is not entirely surprising, especially when considered in the context of the commonly assumed paradigm that the light-element abundance dispersions in globular clusters are driven primarily by pollution from intermediate-mass AGB stars because theoretical Type II SNe and AGB yields tend to converge at $[\text{Fe}/\text{H}] \gtrsim -1.2$ (e.g., see Fig. 22 in Johnson & Pilachowski 2010 and references therein). This means that a cluster like M107, forming from gas polluted by Type II SNe and AGB stars with metallicities near $[\text{Fe}/\text{H}] \sim -1$, should not exhibit the same large $[\text{Al}/\text{Fe}]$ spread seen in stars forming from gas polluted by more metal-poor progenitors. Therefore, the observed small $[\text{Al}/\text{Fe}]$ variations observed in M107 are consistent with its metallicity. However, the average $[\text{Al}/\text{Fe}] = +0.39$ is at least 0.3 dex lower than the predicted yields of the ~ 5 – $6.5 M_{\odot}$ AGB stars that are commonly assumed to be the primary polluters in globular clusters (e.g., Ventura & D'Antona 2009; see also Karakas 2010). The moderate Al enhancement in M107 suggests that the gas from which these stars formed did not exceed an AGB/Type II SN pollution ratio of roughly 20%/80%. This result is compatible with the observed modest extension of M107's O-Na anticorrelation seen in Carretta et al. (2009a).

5.2. α , Fe-Peak, and Neutron-Capture Elements

Although Ti is often enhanced in globular clusters like the lighter, true α elements (e.g., Mg and Ca), its exact nucleosynthetic origin is unclear. However, M107 does not appear to be an

exception, as both the $[\text{Ti I}/\text{Fe}]$ and $[\text{Ti II}/\text{Fe}]$ ratios indicate that cluster stars are enhanced by an average $[\text{Ti}/\text{Fe}] = +0.40$ with a relatively small star-to-star dispersion ($\sigma = 0.10$). Similarly, the Fe-peak elements, traced here by Sc and Ni, are typically not

FIG. 4.—Box plot illustrating $[\text{Al}/\text{Fe}]$ distribution in 13 galactic globular clusters $-2.35 \lesssim [\text{Fe}/\text{H}] \lesssim -0.75$. Clusters are plotted by increasing metallicity. The middle line of each box indicates the median abundance value, and the upper and lower box boundaries represent the third and first quartiles (75th and 25th percentiles) of the data, respectively. The vertical lines represent the full range of abundance values. Suspected outliers (stars with abundances 1.5 times above the third, or below the first interquartile range) are designated by filled circles, and outliers (abundances 3.0 times above the third, or below the first interquartile range) are open circles. M80 from Cavallo et al. (2004); M13 from Johnson et al. (2005); M30, M68, M55, M10, NGC 6752, M12, NGC 288, M4, M71, and NGC 104 from Carretta et al. (2009b); M107 from the current study. See the electronic edition of the *PASP* for a color version of this figure.

enhanced in globular cluster stars and tend to exhibit small star-to-star dispersions. We find that M107 fits this trend, as Ni exhibits no enhancements with $\langle [\text{Ni}/\text{Fe}] \rangle = 0.00$ ($\sigma = 0.09$), on average, and Sc also appears only moderately enhanced at $\langle [\text{Sc}/\text{Fe}] \rangle = +0.13$ with a small star-to-star dispersion ($\sigma = 0.09$). The enhancement of $[\text{Ti}/\text{Fe}]$ and solar-scaled abundance ratios of $[\text{Sc}/\text{Fe}]$ and $[\text{Ni}/\text{Fe}]$ are clearly illustrated in Figure 5, where we show a box plot of all elements measured in this study.

Most stable isotopes of elements heavier than the Fe-peak are produced through either the rapid (*r*) or slow (*s*) neutron-capture process (e.g., see review by Sneden et al. 2008). In general, the heavier elements synthesized via the main component of the *s*-process (e.g., Ba and La) are believed to be primarily produced in lower-mass ($\sim 1\text{--}3 M_{\odot}$) thermally pulsing AGB stars over timescales $\gtrsim 5 \times 10^8$ yr. In contrast, the exact origin of the *r*-process is unknown, but it is believed to be associated with core-collapse SNe, and therefore enrichment should occur on a rapid timescale of $\lesssim 5 \times 10^7$ yr (e.g., see the review by Truran et al. 2002). *R*-process production is often traced through the element Eu, which is produced almost exclusively by the *r*-process.

While the star-to-star dispersion for neutron-capture elements in globular clusters is typically larger than that observed for the α and Fe-peak elements (e.g., see Roederer 2011 and references therein), it is almost always smaller than the variations observed for the lighter elements C through Al. However, on average, most globular clusters have $[\text{Eu}/\text{La}] \gtrsim +0.2$ (e.g., Gratton et al. 2004), which suggests that the clusters formed rapidly and before a significant amount of *s*-process enrichment could occur. M107 exhibits this same trend with $\langle [\text{La}/\text{Fe}] \rangle = +0.41$ ($\sigma = 0.12$), $\langle [\text{Eu}/\text{Fe}] \rangle = +0.73$ ($\sigma = 0.13$), and $\langle [\text{Eu}/\text{La}] \rangle = +0.32$ ($\sigma = 0.17$). Although the $[\text{Eu}/\text{Fe}]$ ratio exhibits the largest abundance

FIG. 5.—Box plot indicating the abundance distribution and star-to-star variation in the measured abundances relative to Fe I, with $\langle \text{Ti} \rangle$ as the mean value of Ti I and Ti II. The plotting designations are the same as Figure 4.

range out of all the elements included in this study, the [Eu/Fe] interquartile range is not appreciably different from the other elements. This suggests that the cluster formed from gas that was well mixed and exhibited a nearly homogeneous composition. Finally, the negligible *s*-process signature indicates that low- and intermediate-mass AGB stars did not contribute strongly to the cluster's primordial composition, which further supports the observed relatively small light-element abundance variations observed here and in previous studies.

6. SUMMARY

We present for the first time moderate-resolution spectroscopic abundances of Fe, Al, Ti, Sc, Ni, La, and Eu for 13 RGB stars in the globular cluster NGC 6171 (M107). All data for this study were obtained at Kitt Peak National Observatory with the WIYN 3.5 m telescope and Hydra multifiber spectrograph using a moderate-resolution ($R \sim 15,000$) echelle grating. The co-added spectra have a $\langle S/N \rangle \sim 80$ and cover a wavelength range from ~ 6460 – 6860 Å. Program stars range in luminosity from the RGB tip to ~ 1 magnitude above the level of the HB.

Effective temperatures and surface gravities for individual stars were estimated using the cluster's distance modulus and $(V - K)_0$ color indices obtained from photometric data. An iterative LTE stellar line analysis code was employed to further modify T_{eff} and microturbulence (v_t) via spectroscopic analyses. With the exception of Al, abundances were determined by equivalent width (EW) analyses. For Al we chose to derive abundances using spectrum synthesis to eliminate possible contamination from nearby CN and metal lines. Input line lists were used for Sc and Eu to provide hyperfine structure and/or isotope broadening corrections. An empirical correction was applied to our La II EW measurements, as no hyperfine line list exists for this line.

Given the low galactic latitude of this cluster and close relative proximity to the galactic center ($b = 23^\circ$ and $R_{\text{GC}} = 3.3$ kpc, respectively), interstellar reddening and extinction can be a possible concern. Reddening values and distance moduli found in literature were not very well constrained, but by assuming a color excess value close to the upper limit found in literature, $E(B - V) \sim 0.46$, we find a near 1:1 correlation between photometric and spectroscopic T_{eff} estimates. Similarly, we chose the smallest available distance modulus, $(m - M)_V = 13.76$, because the larger distance moduli yielded surface gravity values that appeared too low for each star's metallicity and position on the color-magnitude diagram.

We confirm that M107 is moderately metal-rich, with average $[\text{Fe}/\text{H}] = -0.93$ ($\sigma = 0.04$), which is consistent with previous photometric and spectroscopic studies. Program stars indicate a small star-to-star metallicity spread of 0.12 dex, suggesting that M107 is a bona fide monometallic cluster. Carretta et al. (2009a) finds a similar star-to-star spread in

[Fe/H], 0.18 dex, and the same σ value, 0.04, for 33 stars in this cluster. The HB of M107 is dominated by red HB stars ($(B - R)/(B + V + R) = -0.76 \pm 0.08$) and RR Lyrae variables, which would not be unexpected for its metallicity, and lacks a significant population of blue HB and blue hook stars. This may indicate that M107 did not experience strong the helium enrichment that is typically demonstrated by some of the more massive clusters that also tend to exhibit the largest light-element abundance variations.

We find that the [Al/Fe] ratio is enhanced in all cluster stars at $\langle [\text{Al}/\text{Fe}] \rangle = +0.39$ ($\sigma = 0.11$), with only two stars having $[\text{Al}/\text{Fe}] > +0.5$. The baseline $[\text{Al}/\text{Fe}] = +0.24$ is consistent with predicted yields from Type II SNe, but the average [Al/Fe] enhancements are well below the theoretical yields from similar metallicity, intermediate-mass AGB stars. The small star-to-star [Al/Fe] variations observed in M107 follow the trend observed for other clusters of similar metallicity. Similarly, we find that M107 exhibits typical globular cluster abundance ratios with respect to the heavier elements. The surrogate α element tracer Ti is enhanced with $\langle [\text{Ti}/\text{Fe}] \rangle = +0.40$ ($\sigma = 0.10$), and the two Fe-peak elements Sc and Ni exhibit nearly solar-scaled abundance ratios with $\langle [\text{Sc}/\text{Fe}] \rangle = +0.13$ ($\sigma = 0.09$) and $\langle [\text{Ni}/\text{Fe}] \rangle = 0.00$ ($\sigma = 0.09$). Finally, the neutron-capture elements indicate that M107 is *r*-process-rich [$\langle [\text{La}/\text{Fe}] \rangle = +0.41$ ($\sigma = 0.12$), $\langle [\text{Eu}/\text{Fe}] \rangle = +0.73$ ($\sigma = 0.13$), and $\langle [\text{Eu}/\text{La}] \rangle = +0.32$ ($\sigma = 0.17$)] and therefore likely formed quite rapidly. The relatively small star-to-star element variations in this cluster suggest that it did not experience a significant amount of self-enrichment.

We extend gratitude to Diane Harmer for obtaining all observations used in this study. This research makes use of data products from the Two Micron All Sky Survey, which is a joint project of the University of Massachusetts and the Infrared Processing and Analysis Center/California Institute of Technology, funded by the National Aeronautics and Space Administration and the National Science Foundation. This research has also made use of the NASA/IPAC Extragalactic Database (NED) which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration. This work was supported in part by the National Science Foundation through an REU Site Program grant to Tennessee State University, AST-0453557, and Indiana University, AST-0453437. JEO is also grateful for the continuation of support for this study from the Tennessee State University Center of Excellence for Research and Sponsored Programs through the National Science Foundation grant AST-0958267. Support of the College of Arts and Sciences at Indiana University Bloomington for CIJ is gratefully acknowledged. This material is based upon work supported by the National Science Foundation under award No. AST-1003201 to C.I.J.
